## 1 **ABSTRACT**

2 The federal *Moving Ahead for Progress in the 21<sup>st</sup> Century* legislation mandated a performance-  
3 based evaluation approach for transportation projects. Reference travel speed is used as a  
4 benchmark for calculating delay, mobility and reliability statistics in standard industry and  
5 research practice. These reference speeds reflect free-flow (unconstrained) travel conditions on  
6 different facilities. However, the rationale behind the choice of this important parameter is not  
7 entirely established and a few different metrics are adopted.

8 This study provides a basis for benchmarking reference speed for use in mobility and  
9 reliability performance measures. An average driver's perception of reference speed on a  
10 roadway segment is influenced not only by the posted limit but also a few other factors including  
11 road geometry and driving conditions. Therefore, recorded travel time data can be more  
12 reflective of current travel conditions on roadway segments than the posted speed limit. This  
13 research investigates an appropriate reference time window representative of unconstrained  
14 conditions by analyzing all-day travel patterns on different facilities.

15 Researchers find that nighttime hours (9PM-6AM) provide a good representation of  
16 unconstrained travel on both interrupted and uninterrupted flow facilities. When overnight data  
17 are inadequate, they can be supplemented with mid-day (11AM-4PM) unconstrained travel data.  
18 The 85<sup>th</sup> percentile of average speeds within identified time windows is the recommended  
19 reference speed metric for all roadway functional classes. On minor arterial streets, actuation and  
20 priority treatment cause lower nighttime travel speeds, therefore, the 85<sup>th</sup> percentile of  
21 supplemented data (nighttime and mid-day) is more representative of reference travel conditions  
22 on such facilities.

## 1 INTRODUCTION

2 The Moving Ahead for Progress in the 21st Century Act (MAP-21) propelled transportation  
3 system performance measurement to the center-stage within the transportation profession (1).  
4 Several state departments of transportation (DOTs), public and private agencies, and  
5 metropolitan planning organizations (MPOs) have developed measures and techniques to  
6 actively evaluate and address their roadway infrastructure's ability to meet planned objectives.  
7 Among the several approaches targeted toward overall transportation system performance  
8 evaluation, one of the more popular and commonly implemented is the measurement of a  
9 system's mobility and reliability performance. Industry-wide practice in these areas uses a  
10 reference travel time (speed) for calculation of delay, mobility and reliability statistics (2,3).  
11 These reference speeds reflect free-flow (unconstrained) travel conditions. In case of  
12 uninterrupted facilities (e.g., freeways and Interstates), this refers to travel conditions in which  
13 vehicles are not subject to interference from other vehicles and traffic control. For arterial streets,  
14 this refers to no interference from other vehicles but includes traffic control delay as defined in  
15 this study.

16 However, the rationale behind the choice of this important parameter is still not entirely  
17 established and a few different metrics are adopted in practice. A review of current state-of-  
18 practice highlights the different proxies for reference speed used by states and agencies, some of  
19 which are based on the posted speed limit (PSL) on a facility. This approach can serve to some  
20 extent in situations where recorded travel data are unavailable or inadequate. However, an  
21 average driver's perception of reference speed on a roadway segment is influenced not only by  
22 the posted limit but also a few other factors including road geometry, driving conditions and  
23 presence of traffic signals. Therefore, deriving applicable reference speeds from actual travel  
24 time data may be superior to the use of a reference speed value based solely on a fixed PSL.  
25 Recorded travel time data can be more reflective of current operational conditions on roadway  
26 segments than the PSL.

27 It is worth recalling at this point that travel time and speed have complimentary  
28 relationships in terms of percentiles. For example, the 95<sup>th</sup> percentile travel time corresponds to  
29 the 5<sup>th</sup> percentile travel speed and vice-versa. Reference speed typically represents unconstrained  
30 travel conditions on roadways and its choice on any facility can affect the ability of the  
31 corresponding measures to accurately capture actual system performance. Depending on the  
32 magnitude of difference in actual and adopted reference values, the reported measures can mis-  
33 approximate mobility measures by 20-25% and even higher for reliability measures (4).

34 This research investigates an appropriate reference time window representative of  
35 unconstrained travel conditions by analyzing all-day travel patterns. This was done for both  
36 uninterrupted flow facilities (interstates and freeways) and interrupted flow facilities (major and  
37 minor urban arterials) because of inherent differences in their travel behavior and characteristics.  
38 Using probe-based travel time data from INRIX<sup>®</sup>, a private-sector data provider, the analysis  
39 incorporated different urban areas to provide a more balanced representation of travel patterns  
40 and minimize any sampling bias. Researchers also examined a theoretical basis for the choice of  
41 a percentile measure for defining reference speed.

## 1 BACKGROUND AND LITERATURE REVIEW

2 Opinions and practice regarding the choice of reference speed vary among states and agencies.  
3 While some adopt the PSL on a facility as its reference speed based on the rationale that this is  
4 the legal upper limit on how fast drivers can travel on that facility, others prefer to use PSL plus  
5 five mph speed as the reference speed. The latter is based on the rationale that during  
6 unconstrained hours, when the traffic is light, drivers are free to travel at a speed they feel is  
7 reasonable while still remaining within legal bounds. Most travelers tend to drive marginally  
8 above the speed limit which allows them to travel slightly faster while still staying within the  
9 allowable range not usually ticketed.

10 Because reference speed is not attainable during several hours of a typical day, some  
11 agencies use maximum throughput speeds to calculate mobility measures like area- or state-wide  
12 vehicle-hours of delay (5). The maximum throughput speeds are usually between 70%-85% of  
13 PSL and are realized when the greatest number of vehicles occupy the highway at a time.  
14 Because efficient performance measurement can use rich real-world data, some other agencies  
15 prefer to derive reference speeds directly from their available data sets. This removes the  
16 potential effects of an arbitrary choice of reference speeds. However, different metrics (e.g.,  
17 mean- or median-based speed threshold, 75<sup>th</sup> or 80<sup>th</sup> percentile speed or maximum throughput  
18 speed, etc.) are used for this purpose based on the agency's performance measurement goals. The  
19 current research is motivated by the lack of standard practice in this area of performance  
20 measurement.

21 Using a fixed value such as PSL as the reference speed can have some limitations. The  
22 reference speed, as perceived by travelers, is influenced by the posted limit combined with a few  
23 other factors such as road geometry and driving conditions. For example, travelers may be  
24 comfortable traveling faster than the PSL during unconstrained hours on a segment of roadway  
25 with standard 12 feet lanes, good sight distances and other favorable travel conditions. But they  
26 may travel at a slightly lower speed (closer to the PSL) on segments of the same roadway with  
27 less favorable conditions (narrow lanes, lower sight distances, poor visibility, etc.) during the  
28 same unconstrained hours. Essentially, different segments of the same roadway with the same  
29 PSL may have different reference speeds depending on their geometric and operational  
30 characteristics.

31 Identifying applicable reference speeds for different segments of roadways based on  
32 actual travel speed data can be useful. This will enable better reflection of operating conditions  
33 on various sections without generalizing conditions over all road sections of a roadway which  
34 has been assigned an arbitrary reference value. The National Cooperative Highway Research  
35 Program (NCHRP) report 618 recommends evaluating such operational considerations while  
36 determining the appropriate reference speed for delay and index computations (4).

### 37 Current State-of-the Practice

38 The choice of reference speed for performance measurement is not uniform among states and  
39 agencies in the United States. Different agencies adopt different proxies to assign reference  
40 speeds to their facilities as illustrated in Table 1.

1 **TABLE 1 Reference Speed Definitions Adopted by Different Agencies**

Agency/Standard	Definition for Reference Speed
Highway Capacity Manual (HCM) (6)	<ul style="list-style-type: none"> <li>• The theoretical speed when the density and flow rate on a study segment are both zero.</li> <li>• The prevailing speed on freeways at flow rates between 0 and 1,000 passenger cars per hour per lane (pc/h/ln). (HCM 2010, pg. 9-8)</li> <li>• In the context of urban streets, reference speed is “...the average running (midblock) speed of through automobiles under low-volume conditions and not delayed by traffic control devices or other vehicles.” (HCM 2010, pg. 17-32)</li> </ul>
Texas A&M Transportation Institute (TTI) (7)	<ul style="list-style-type: none"> <li>• In line with the HCM definition of <i>reference speed</i>, TTI has adopted the term <i>uncongested speed</i> in the context of arterial streets to mean the “...<i>average speed that can be accommodated under relatively low traffic volumes (i.e., no vehicle interactions) on a uniform roadway segment under prevailing roadway and traffic conditions.</i>”</li> <li>• However, as opposed to the HCM, this definition includes the prevailing traffic signal control delay that occurs in light traffic.</li> </ul>
Florida DOT (8)	<ul style="list-style-type: none"> <li>• Field-measured average speed under low volume conditions, when drivers are not constrained by other vehicles, roadway geometry or traffic control.</li> <li>• In absence of field data, reference speed can be estimated at five mph above the posted speed limit.</li> </ul>

2 Some agencies, cities and MPOs adopt the PSL or PSL plus five mph speed as reference speed  
 3 for their use (5,7-16). Table 2 provides examples to show the current use of different proxies for  
 4 reference speed in the United States.

5 **TABLE 2 Different Measures of Reference Speed Adopted by U.S. Agencies/ States**

Measure used as Reference Speed	State DOT/ MPO
Posted speed limit	Missouri, Nebraska, Nevada, Ohio (defines reference speed as at or near posted limit), Virginia, Wisconsin, Washington
Posted limit plus five	Oregon, Florida
Reference speed*	California, Maryland, Chicago (CMAP)**, New York (NYMTC), Texas

6 \*the term is not specified in a numerical or temporal boundary definition

7 \*\*Chicago Metropolitan Agency for Planning (CMAP) measures reference travel speed based  
 8 on average travel speeds between 8:00 PM and 5:30 AM (15)

9 Changes in operational characteristics result in changes in reference speeds on different segments  
 10 of a roadway with the same PSL. For this reason, adopting a common reference speed may not  
 11 provide a good representation of the operational characteristics on all segments of the roadway,  
 12 particularly when there are a large number of segments. When aggregated at an urban area level,  
 13 this choice of reference can result in significant differences in reported travel performance  
 14 measures.

## 1 **METHODOLOGY AND DATA DESCRIPTION**

2 There is a lack of general agreement on what delay measurement intends to report and the  
3 benchmark used for it, therefore, this study investigates what the reference speed on a facility is  
4 under all favorable conditions. It does not set a threshold for “reasonable expectancy” and  
5 defines reference speed accordingly. This will enable more consistency in performance  
6 measurement reporting activities as the benchmark is set at an absolute scale and not a relative  
7 one defined by the user or agency.

8 The data for this study come from the INRIX<sup>®</sup> XD<sup>™</sup> database. The XD segments, as  
9 denoted by INRIX<sup>®</sup>, are similar in nature to traffic message channels (TMCs) but typically are  
10 shorter and have higher spatial resolution (up to 820 feet [250 meters] on major roads) compared  
11 to typical TMC resolutions of 1-3 miles. For the available dataset, these XD segments are  
12 typically 1 mile or less in length. The dataset used in this study consists of travel time data for  
13 calendar year 2014 from several urban areas in Texas with a few suburban and rural areas also  
14 included. The database consists of 10,584 freeway segments and 17,057 arterial segments.

15 Figure 1 shows the roadways for all four facility types (interstates, freeways, major and  
16 minor arterials) used in this study on the state map of Texas.

1

2 **FIGURE 1 Texas state map showing all roadway segments used in the study.**

3 INRIX® provides annual average travel times for each 15-minute interval of each day of the  
 4 week. For example, a data entry for 01:15 AM on Monday provides the annual average travel  
 5 time of all vehicles traveling on that segment between 01:15 AM and 01:30 AM. This equates to  
 6 672 “cells” of travel time data (4 fifteen-minute intervals per hour\*24 hours per day\*7 days per

1 week) for each XD segment. The following are some key highlights from initial examination of  
2 the data:

- 3 • Travel times have been collected using the vehicle probe technique, which captures  
4 vehicle travel speeds based on cellular and Global Positioning System (GPS) data.
- 5 • The database consists of “point-paired” data which capture the vehicle travel times  
6 between points of detection, and not the vehicle spot speeds at individual locations along  
7 any road segment. In this respect, these data are representative of space mean speed  
8 commonly used in transportation studies.
- 9 • The 15-minute aggregated travel times have been converted to respective travel speeds  
10 for each segment based on the segment’s length. Conversion from travel times to speeds  
11 makes understanding the data easier and more intuitive without losing any information.
- 12 • Data availability challenges were experienced in some cases. Arterial segments are  
13 observed to suffer from lack of data to varying extents during traditional unconstrained  
14 hours of the day (9PM-6AM). This is observed particularly for rural arterial segments  
15 which witness very sparse traffic during such periods of the day.
- 16 • About 23% of all arterial segments (3,923 of 17,057) and 28% of minor arterial segments  
17 (1,587 of 5,643) were observed to have less than 50% of data available during usual  
18 unconstrained hours (i.e., fewer than 90 of 180 cells filled for the period 9PM-6AM on all  
19 weekdays).
- 20 • For segments with sparse data (less than 50% availability), an additional time window for  
21 unconstrained travel with higher data availability was investigated. Otherwise the  
22 corresponding results can be subject to high fluctuation and may not be dependable.

23 The sequence of data analysis for identification of an unconstrained travel window broadly  
24 consists of the following six steps:

- 25 ▪ **Step 1:** Visually inspect all-day 15-minute average travel speed pattern to identify  
26 candidate time windows for each class of transportation facility
- 27 ▪ **Step 2:** Check for data adequacy within identified time windows
- 28 ▪ **Step 3:** Use the coefficient of variation to help identify appropriate time windows and  
29 eliminate windows with higher variability in travel speeds
- 30 ▪ **Step 4:** Select time window with lower variability if alternate windows have statistically  
31 indifferent reference speeds
- 32 ▪ **Step 5:** Examine statistical significance of effect of using common time windows for all  
33 facility types, and incremental benefit of using weekend travel data in addition to regular  
34 workweek travel data
- 35 ▪ **Step 6:** Investigate data distribution and choice of appropriate percentile to define  
36 reference speed within identified time windows

## 37 DATA ANALYSIS AND RESULTS

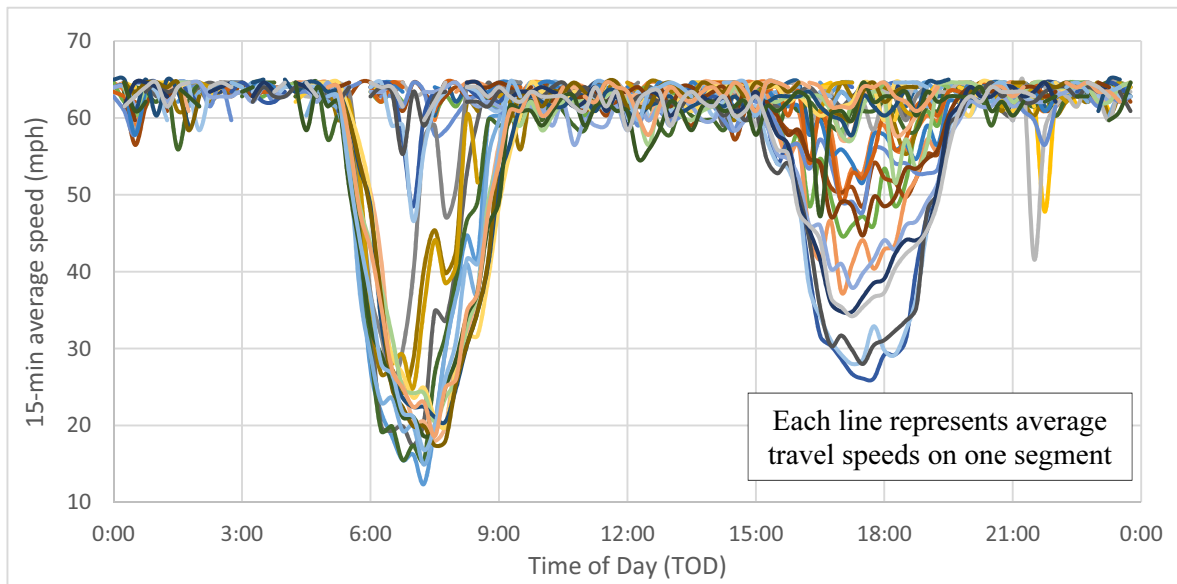

### 38 Step 1 and Step 2: Visual Inspection of All-Day Travel Patterns and Check for Data 39 Adequacy

40 The preliminary step in narrowing candidate travel windows with speeds potentially close to the  
41 facility’s reference speed is visually inspecting travel speed patterns for all-day travel. This gives  
42 an estimate of smaller temporal windows that can be investigated further. This exercise was  
43 performed for all uninterrupted and interrupted flow facilities included in this study. Figure 2(a)

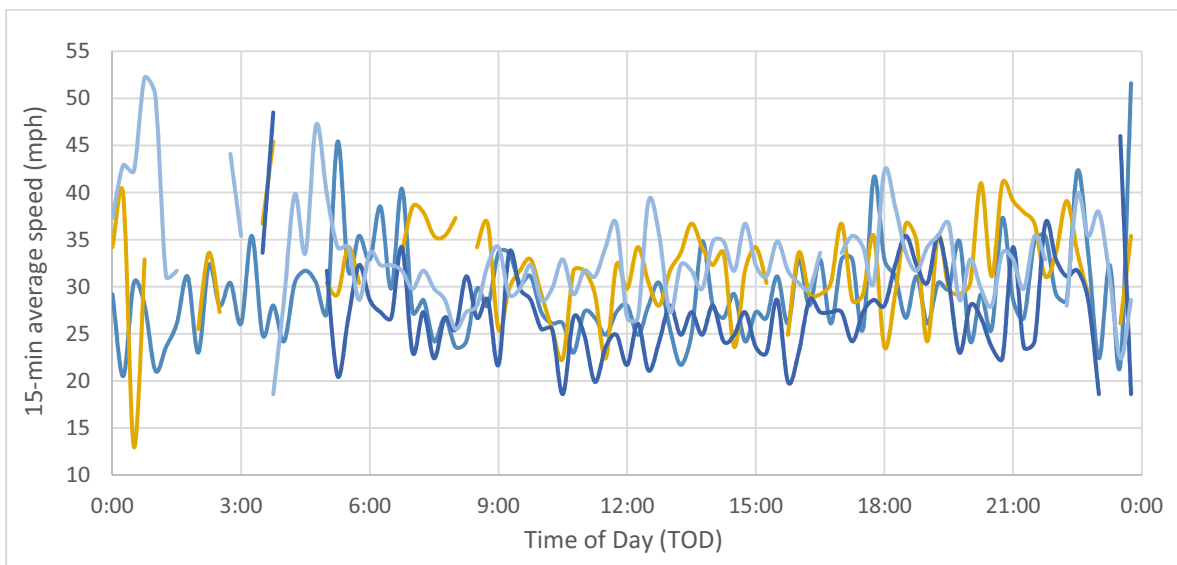

1 and Figure 2(b) show typical all-day travel speed patterns for a few freeway and arterial street  
 2 facilities respectively. Each line represents annual average 15-minute travel speeds throughout  
 3 the day on one segment. It should be noted that the speed patterns shown are line graphs instead  
 4 of point scatter plots just for ease of observation. It is understood that because of 15-minute  
 5 aggregation, the data are not continuous in the true sense, which the line graphs may suggest.

6 As shown in Figure 2(a), freeway facilities tend to show significantly lower speeds with  
 7 onset of peak period congestion during morning and evening peaks. Although speeds tend to  
 8 decrease for interrupted flow facilities also, the magnitude of drop in speed during peak periods  
 9 is smaller. Figure 2(b) also shows that some arterial street segments lacked travel time data  
 10 during overnight period.

11 **(a) Travel speed variation by time of day for freeway facilities.**

12 **(b) Travel speed variation by time of day for arterial street facilities.**

14 **FIGURE 2 Travel speed variation on uninterrupted and interrupted flow facilities.**

1 Visual inspection led to a few candidate time windows of unconstrained travel for consideration.  
 2 Table 3 provides details on average data availability for different facility types during two such  
 3 unconstrained travel windows. This data availability is expressed in terms of the average  
 4 percentage of cells filled out of 180 cells (for 9PM-6AM) or 120 cells (for 11PM-5AM).

5 **TABLE 3 Average Percentage Data Availability for Different Facility Types during**  
 6 **Unconstrained Travel Windows**

Facility Type		Percentage Data Availability Within Specified Time Window	
		11 PM – 5 AM	9 PM – 6 AM
Uninterrupted Flow	Interstate	91.8	96.2
	Freeway	79.5	86.9
Interrupted Flow	Major Arterial	66.1	78.1
	Minor Arterial	56.8	65.2

7 Even within an expanded window of 9PM-6AM, a proportion of arterial streets did not have  
 8 sufficient data to draw useful inferences. In particular, about 28% of minor arterial segments  
 9 (1,587 of 5,643) had less than 50% of 180 cells of data filled for the period 9PM-6AM.

10 For such facilities, an additional mid-day time window was required because conclusions  
 11 based on very sparse data can be subject to high fluctuations and may not be dependable for  
 12 sustained performance measurement. This time window was determined to be 11AM-4PM for  
 13 which the next section provides more details in terms of data availability and variability within  
 14 the time window.

15 **Step 3 and Step 4: Determination of Appropriate Time Windows and Selection between**  
 16 **Candidate Windows**

17 Travel speeds can achieve high values during different parts of the day, however, it is difficult  
 18 and impractical to assign several distinct and spaced out travel time windows as reference speed  
 19 time windows. Also, although a relatively high average speed may be observed during a few 15-  
 20 minute windows in a short period of time, it is not very meaningful to consider such spikes in  
 21 speeds if these speeds cannot be maintained over a longer interval of time. Therefore, a balance  
 22 between the magnitude of average 15-minute travel speeds and their consistency over a  
 23 reasonable duration is necessary.

24 As a result, the all-day travel patterns were observed in conjunction with the coefficient  
 25 of variation of average travel speeds. The coefficient of variation, CV, is the ratio of standard  
 26 deviation ( $\sigma$ ) and the mean ( $\mu$ ).

27 
$$CV = \frac{\sigma}{\mu}$$

28 Mean and standard deviation of travel speed were calculated on each segment for  
 29 different periods of the day. For example, if the mean speed was calculated on a segment for the  
 30 duration 6AM-10AM on all weekdays (average of 80 cell values [4 fifteen-min intervals per  
 31 hour\*4 hours\*5 weekdays]), the standard deviation of speeds for the same time period was also

1 computed to obtain the CV for the time period. The following are a few key highlights of this  
 2 step of analysis:

- 3 • The coefficient of variation of travel speed was calculated using values for standard  
 4 deviation and mean for all time windows resulting from step 1. Time periods with CV  
 5 greater than 10% were not considered further.
- 6 • Unconstrained travel time windows with high values of mean and 85<sup>th</sup> percentile speeds  
 7 were investigated among time windows with CV ≤ 10%. As shown in Table 4, these time  
 8 windows are slightly different depending on the type of transportation facility.

9 **TABLE 4 Unconstrained Travel Windows for Different Facility Types**

Facility Type		Candidate Time Windows for Unconstrained Travel	
		Daytime Window(s)	Nighttime Window(s)
Uninterrupted Flow	Interstate and Freeway	9 AM-11 AM, 1 PM-3 PM	7 PM-9 PM, 10 PM-6 AM, 2 AM-5 AM
Interrupted Flow	Major Arterial	10 AM-1 PM, 2 PM-4 PM	9 PM-6 AM
	Minor Arterial	8 AM-10 AM, 11 AM-4 PM	10 AM-12 AM, 2 AM-6 AM

10 CV was preferred as a metric over standard deviation because it normalizes the variability in  
 11 speeds with respect to the mean speed. For example, while a freeway facility can have a  
 12 reference speed of 60 mph, an arterial facility can have it as 40 mph, and CV is able to account  
 13 for these different levels of base speeds better than a fixed value of standard deviation.  
 14 Considering all roadway segments, the mean CV was found to be 5% for uninterrupted flow  
 15 facilities during the chosen reference travel time window (9PM-6AM), while it was 8% for  
 16 interrupted flow facilities.

17 **Step 5: Check for Statistical Effect of Use of Alternate Time Windows**

18 *Use of Weekend Travel Data Along With Weekday Travel Data*

19 There is no common standard among agencies for use of weekend travel data. Following the  
 20 same procedure (calculating mean and standard deviation to get CV and limiting CV to a  
 21 maximum value of 10%), the reference travel time window during weekends (Saturday and  
 22 Sunday) was identified as 5AM-9AM. This time period was found to be consistent with current  
 23 practice of several agencies which use weekend data to define reference speed (13). The  
 24 following are a few key observations for this step of analysis:

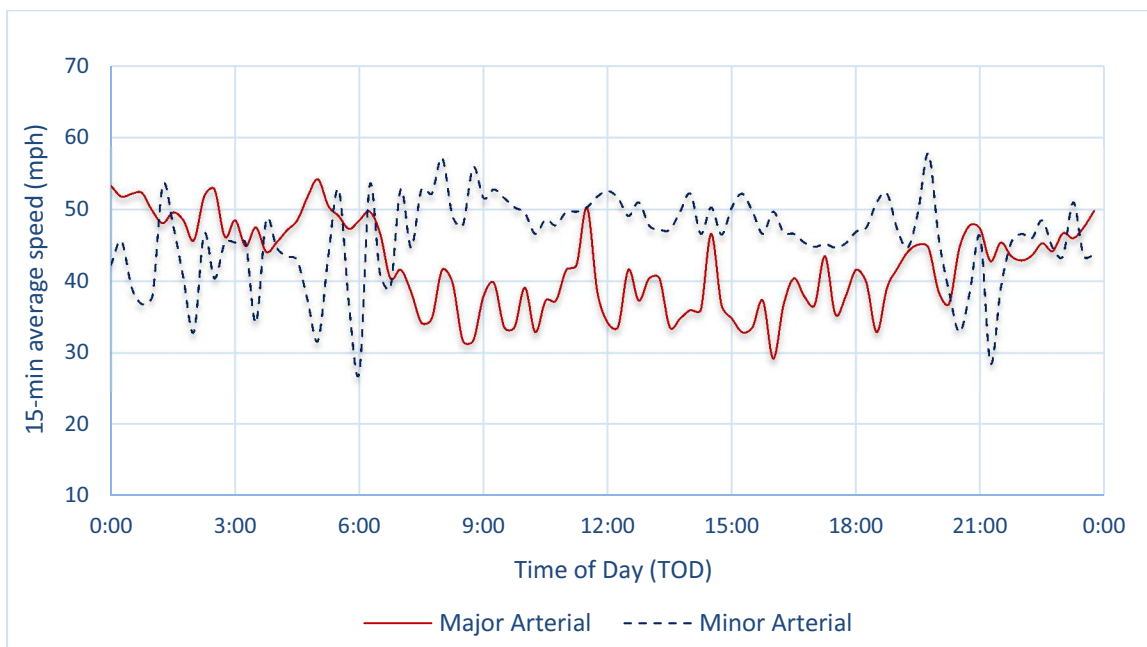

- 25 • For 16,225 of 17,057 arterial segments and for 9,686 of 10,584 freeway segments,  
 26 including the weekend unconstrained travel (5AM-9AM) did not have a statistically  
 27 significant effect on reference speeds.
- 28 • For the small portion of segments that showed numerical increase in values of reference  
 29 speeds when weekend data were included, the highest magnitude of increase compared to  
 30 “weekday-only” data was 1.7 mph and most of them ranged between no increase to an  
 31 increase of 1 mph.

1 This shows that for most transportation facilities, as long as the reference travel time windows  
 2 are chosen appropriately, the reference speed does not change significantly when weekend travel  
 3 data are included. This is intuitive because travel behavior for a driver familiar with the facility  
 4 should not change significantly during what are typically low traffic periods when traffic  
 5 pressure does not affect driving behavior.

6 *Arterial Street Type (Major vs. Minor) Effect on Unconstrained Travel Window*

7 The travel time pattern is different for major and minor arterials. Figure 3 shows the variation of  
 8 average 15-minute travel speed throughout a day for major and minor arterial street segments  
 9 separately. Each data point is the average travel speed for all major arterial segments (solid line)  
 10 or minor arterial segments (dotted line) for each 15-minute period.

11 The average travel speeds on all major arterial segments follow a pattern similar to  
 12 freeways, wherein the overnight period travel speeds are higher than the rest of the day.  
 13 However, minor arterial streets follow a slightly different pattern wherein the nighttime travel  
 14 speeds are lower than some parts of daytime travel and there is higher variability of average  
 15 speeds within the overnight time window. This typically happens because traffic on major  
 16 arterial streets is given priority over minor street traffic during overnight period. For example, if  
 17 the signals are actuated, the minor street does not receive a green indication until a vehicular call  
 18 is placed through detection. Even when the signals are pre-timed, the major street receives most  
 19 of the green phase, and therefore, minor street vehicles are delayed although there is light traffic  
 20 on minor streets. Minor street vehicles which are fortunate to arrive at the signal when it is green  
 21 register lower travel times (higher average speeds), while those which need to wait for the green  
 22 indication experience a higher travel time. This gives rise to an overall higher fluctuation in  
 23 travel time as seen in the left portion of the graph (12AM-6AM) for minor arterial segments.

24

25 **FIGURE 3 Travel speed variation on major and minor arterial street facilities.**

26

### 1 *Use of a Common Time Window for All Facility Types*

2 Data adequacy can be a challenge during nighttime hours. As seen in Table 3, to improve  
3 average data availability for arterial segments, the reference travel window was expanded from  
4 11PM-5AM to 9PM-6AM. The following are a few key observations regarding this expansion:

- 5 • It was found that for 9,529 of 10,584 freeway segments, changing from the 11PM-5AM  
6 window to 9PM-6AM window does not have a statistically significant effect on reference  
7 speeds.
- 8 • For the remaining segments in which the speed differences were found to be significant,  
9 the maximum magnitude of difference was 1.8 mph. This can have an effect on delay and  
10 mobility metrics depending on the length of the segment and the volume of traffic on it.  
11 This aspect is not explored in this research and can be studied further.
- 12 • Considering all segments irrespective of facility type, it is found that the average value of  
13 CV remains below 10% when the data availability for the 9PM-6AM period is at least  
14 50% (i.e., at least 90 of 180 cells are filled). When the data availability falls below 50%  
15 the average CV stays above 12%.
- 16 • For facilities which have less than 50% data within the traditional nighttime period  
17 (9PM-6AM), nighttime data can be supplemented with mid-day data (11AM-4PM) to  
18 derive a more consistent (less variable) reference speed.

### 19 **Step 6: Data Distribution and Selection of Appropriate Percentile to Define Reference** 20 **Speed**

21 A vast majority of transportation data, particularly traffic speed data, start approaching a normal  
22 distribution as the level of data aggregation increases. With increasing aggregation, the travel  
23 time data start to move from a right skew (a longer right tail) to a more symmetric normal  
24 distribution. Also, the travel speed distribution moves from a left skew distribution to a normal  
25 distribution. This is experienced even more during unconstrained travel windows when vehicles  
26 travel at similar speeds and the variability is limited. A few assumptions regularly used in  
27 transportation engineering are based on normal distribution of data. For example, the basis  
28 behind using the 85<sup>th</sup> percentile value to assign speed limit on roadways is that the 85<sup>th</sup> percentile  
29 captures data within two standard deviations of the mean (and the median if the data is perfectly  
30 normal). A few other related concepts are discussed in more detail in this section.

31 Two of the more popular methods to check for normality of data are the histogram and  
32 the cumulative distribution function plot (CDF plot). The 15-minute average speed data from  
33 preferred unconstrained travel time windows (9PM-6AM for freeways and major arterial streets;  
34 plus 11AM-4PM for minor arterial streets) were used to obtain their histogram and CDF plots.  
35 As shown in Figure 4, the results indicate that within the chosen reference travel windows, the  
36 data follow a normal distribution very closely. The corresponding cumulative distribution  
37 function plot is shown in Figure 4(b). The quantiles obtained from the INRIX<sup>®</sup> speed data are  
38 plotted along with the standard normal distribution quantiles, thus providing a side-by-side  
39 comparison to check for normality of data. The dashed line signifies normal distribution  
40 quantiles and the solid line represents quantiles for the INRIX<sup>®</sup> speed data.

2 **(a) Histogram of average speeds on a freeway segment (9PM-6AM, Mon-Fri).**

3

4 **(b) CDF plot of average speeds on a freeway segment (9PM-6AM, Mon-Fri).**

5 **FIGURE 4 Histogram and CDF plot of average speeds on uninterrupted flow facilities.**

6 A chi-square test was performed to check for goodness of fit to a normal distribution. Major  
 7 arterial streets showed the highest conformity to a normal distribution (10,161 of 10,927  
 8 segments [93%]) followed by uninterrupted flow facilities (91%), while approximately 68% of  
 9 minor arterial segments (4,167 of 6,130) were found to follow the normal distribution. Travel  
 10 speed data on most facility types follow a normal distribution during unconstrained travel time  
 11 windows. The data for minor arterials show a slight left skew which indicates that there is a  
 12 relatively higher proportion of slower speeds on minor arterials compared to other facility types.  
 13 One of the reasons for this observation can be that the reference time window for minor arterials  
 14 consists of a daytime window also, and therefore can witness some slower speeds relative to  
 15 traditional nighttime hours for the other two facility types. Moreover, compared to the major  
 16 street, a higher portion of vehicles on the minor street is likely to witness red signal on arrival,  
 17 thereby reducing the average travel speed.

1 The literature (17,18) suggests that the reasons for choosing the 85<sup>th</sup> percentile for  
2 defining reference speed on transportation facilities include:

- 3 i. The gradient (slope) of the cumulative distribution curve changes at this percentile value.  
4 The gradient at or below this point is relatively sharp, while it becomes more gentle after  
5 this point.
- 6 ii. 15% of travelers are considered to be a fair number traveling in a more  
7 favorable/uncongested condition.
- 8 iii. The 85<sup>th</sup> percentile value approximates mean speed plus one standard deviation of speeds  
9 if they are normally distributed, and thus includes 68% of the total data.

10 Another important rationale behind adopting the 85<sup>th</sup> percentile for defining reference speed in  
11 this study is that the data used are 15-minute aggregated averages. This aggregation process  
12 removes most of the driver-to-driver variation and the effects of very high individual speeds are  
13 minimized. The distribution of 15-minute average speeds indicates that groups of drivers  
14 (platoons of vehicles) are making different decisions in actuation and priority treatment scenarios  
15 as discussed in earlier sections. Because this analysis focuses on speeds that represent  
16 unconstrained conditions, and it is difficult to know from aggregated speeds why drivers are  
17 making different driving decisions, a higher percentile is a better reflection of “actual  
18 unconstrained” conditions. Moreover, the point of inflection (gradient change) seems to lie close  
19 to the 85<sup>th</sup> percentile for the INRIX<sup>®</sup> travel speed database as well [see Figure 4(b)]. Basing the  
20 percentile choice on the phenomenon of gradient change at that specific percentile seems  
21 rational. It suggests that the rate at which more people traveling at increasing speeds are being  
22 added to the sample remains constant until this percentile value, after which that rate drops,  
23 meaning these faster motorists are getting added at a slower rate.

24 Another option would be to use the mean travel speed (or 50<sup>th</sup> percentile travel speed for  
25 normal distribution) during unconstrained conditions as the reference speed. Therefore  
26 researchers also examined the difference between the 85<sup>th</sup> percentile and the 50<sup>th</sup> percentile speed  
27 during unconstrained travel conditions. The two speeds were nearly identical and thus the 85<sup>th</sup>  
28 percentile was used based on the theoretical background discussed above.

## 29 **RECOMMENDATIONS**

30 Depending on the level of data availability, this research suggests use of one among two alternate  
31 time windows of unconstrained travel identified based on all-day travel patterns. The primary  
32 window is 9PM-6AM on weekdays for all segments which have at least 50% data availability  
33 within this time period. Considering 15-minute data aggregation, this equates to at least 90 cells  
34 filled out of 180. For facilities with lower data availability, this time window should be  
35 supplemented with mid-day (11AM-4PM) data which can help lower the variability of travel  
36 speed compared to nighttime data alone. Weekend travel data did not significantly impact  
37 reference speed, therefore, it is recommended to not include it in analysis while determining  
38 reference speed to reduce computational requirements and complexity.

39 The 85<sup>th</sup> percentile value of aggregated travel speeds is a reasonable measure of reference  
40 speed which can be used for performance measurement activities. A snapshot of the key  
41 recommendations is provided in Table 5.

42

1 **TABLE 5 Key Recommendations of the Study**

<b>Data Availability during 9PM-6AM Time Window</b>	<b>Recommended Reference Travel Time Window</b>	<b>Recommended Reference Speed Percentile</b>	<b>Notes</b>
≥ 50 percent	9 PM – 6 AM weekdays (Mon-Fri)	85 <sup>th</sup> percentile of average speeds within chosen time window	Consistent, less variable data; conformity to normal distribution
< 50 percent	9 PM – 6 AM weekdays (Mon-Fri) + 11 AM – 4 PM weekdays (Mon-Fri)		Left skew in speed distribution; low data availability and high variability during nighttime period

4 **CONCLUSIONS**

5 The reference speed represents unconstrained travel conditions on transportation facilities and  
 6 can be measured during daily temporal windows when the driver has a choice of travel speed  
 7 unimpeded by other travelers. The purpose of this study is to provide a basis for benchmarking  
 8 reference speed on transportation facilities for use in mobility and reliability performance  
 9 measures.

10 Use of PSL or PSL+5 as reference speed has advantages of being easy to obtain and  
 11 stable. However, a reference speed based on actual travel time (speed) data instead of a fixed  
 12 reference (such as the PSL) has advantages of being adaptive, updateable (on a periodic basis)  
 13 and a closer representation of prevailing operational conditions and driver experience. This also  
 14 does away with the need for inventory data (for PSL) in addition to a speed database. Based on  
 15 this study, the 85<sup>th</sup> percentile of average 15-minute speeds during 9PM-6AM is recommended as  
 16 the reference travel speed when data availability for this period is at least 50%. For lower data  
 17 availability, this data should be supplemented with midday travel data during 11AM-4PM. On  
 18 minor arterial streets, the 85<sup>th</sup> percentile of supplemented data (nighttime and mid-day) is more  
 19 representative of reference travel conditions.

20 As more robust and granular datasets become available, further study can examine the  
 21 sensitivity of derived reference speeds to level of data disaggregation. Parameters such as the  
 22 coefficient of variation may need to be adjusted accordingly (e.g., lower data aggregation may  
 23 warrant higher CV). It can be expected that more granular data (low degree of data aggregation)  
 24 can provide more insights into all-day travel patterns. However, care should be exercised while  
 25 making tradeoffs between data interpretability, ease-of-analysis and associated marginal  
 26 information. As discussed earlier, several distantly spaced out time windows of unconstrained  
 27 travel throughout the day may be informative in terms of unconstrained travel but such an  
 28 approach may not be practically applicable or useful. The balance between adequacy of data and  
 29 its variability within identified time windows should be considered while conducting  
 30 performance measurement analyses. The recommended approach can also aid in improving the

1 ability to conduct system performance evaluation with just the travel time database, without  
2 requiring additional information about facility type. This can make the exercise more efficient  
3 and implementable in the long run.

#### 4 ACKNOWLEDGEMENTS

5 The authors would like to thank the sponsors of the Mobility Monitoring in Urban Transportation  
6 (MMUT) Federal Highway Administration (FHWA) pooled fund study who sponsored and  
7 provided data used for this study. The MMUT pooled fund sponsors include FHWA and 15 state  
8 DOTs (California, Colorado, Connecticut, Florida, Illinois, Kentucky, Maryland, Minnesota,  
9 New York, North Carolina, Oregon, South Carolina, Texas, Virginia, and Washington). The  
10 authors would also like to thank Dr. Yunlong Zhang for his useful insights during this study.
